Reporting Period: The results reported here are from work conducted October 2004 to August 2005.

ABSTRACT

The ability to identify accurately and track the strains of an important infectious agent causing a plant disease is fundamental to the surveillance and management of that disease. Therefore, it is critical that we determine what type of *Xylella fastidiosa* (*Xf*) disease reservoir exists in uncultivated habitats and identify potential new variants of *Xf* and their host plants. Our plant collection and xylem extraction efforts have targeted native and naturalized plants in riparian habitats that may harbor *Xf* which is spread from cultivated plants such as grapes by infected blue green sharpshooter (BGSS), *Graphocephala atropunctata* (Signoret) as they move from the riparian vegetation into the vineyards and adjacent plant communities (Purcell 1975). In order to detect and characterize the *Xf* strains from field collected plants, we have first developed a protocol using the real-time polymerase chain reaction (PCR), which has been proven to detect *Xf* at much lower levels than is possible with traditional PCR, and is a one step process reducing the possibility of error (Oliveira et al. 2002, Bextine and Miller 2005). Furthermore, we are using a technique for whole genome amplification which allows us to boost the amount of DNA in low concentration samples so that traditional PCR can be used to amplify and sequence a series of genes. We have detected *Xf* and determined the strain in several common native plant species, including *Encelia farinosa* (brittlebush), *Xanthium strumarium* (cocklebur), *Salvia mellifera* (black sage), *Pluchea odorata* (sweetscent) and *Vitis girdiana* (wild grape). This information is essential for fully understanding the potential for recombination and the generation of new strains. The results of this project will allow for a rational control of the pathogen by either planting or removing particular host plants in the proximity of the *Xf* reservoirs.

INTRODUCTION

Little is known about the potential reservoir of *Xf* contained in native and naturalized plants. Since the insect vectors of *Xf* move freely between cultivated and uncultivated areas, an accurate identification of these *Xf* variants is critical to our understanding of the epidemiology of this disease, and hence to its control. We are using the Multilocus Sequence Typing (MLST) as the basis 1) to unambiguously and uniquely characterize *Xf* strains and clonal diversity, 2) to associate an *Xf* strain and clone with its host plant(s), and 3) to associate an *Xf* strain with its geographic location. MLST is a technique that is currently used to characterize strains and clones of 12 different human bacterial pathogens and to trace their epidemiology based on differences in their nucleotide sequences in one or more genes (<http://www.mlst.net/mixc/further.asp>) (Maiden *et al.* 1998, Enright and Spratt, 1999). In a related project funded by UC DANR, this technique is being used to document within and among-strain variation in *Xf* using the DNA sequence of seven target genes found in all *Xf* strains (Sally *et al.*, in press). The MLST site for *Xylella* (www.mlst.net) will be functional within the next six months (Sally pers. com). The genes used were chosen based on their informative pattern of evolution, and they are distributed throughout the *Xf* genome, summing to 9,307 base pairs. We are using the results of this project to characterize those strains we encounter in the riparian plants and in the BGSS, *Graphocephala atropunctata* (Signoret).

OBJECTIVES

1. Collect *Xf* samples from a diversity of native and naturalized introduced plants in and around the riparian zones in southern California
2. Collect *Xf* samples from adult BGSS
3. Characterize the *Xylella* strains that are recovered using MLST
4. Determine the associations between specific *Xf* strains, their plant hosts, and their geographic distributions

RESULTS

We have sampled a range of riparian plant species known to be host to BGSS or to harbor *Xf* (Purcell 1975, 1976) from riparian sites and sites near citrus groves and cultivated grapes in southern California. The plants in Table 1 were collected from October 2004 – August 2005. All of the plants listed as native are native to the continental United States, except those noted as being native to Central and South America. Xylem was extracted by the pressure bomb method. Plants were identified by botanist Andrew Sanders (UC, Riverside Herbarium) with reference to the Jepson Manual (Hickman 1993). Adult BGSS were collected from a riparian site in August of 2005; only the head was processed in order to avoid diluting the sample with additional insect DNA. DNeasy Plant or Tissue Extraction kits (Qiagen, Valencia, CA USA) were used to extract DNA. We performed real-time PCR using *Xf* specific ITS primers (*Xf1*) (Schaad *et al.* 2002) in order to determine the

presence or absence of the bacteria. The number of *Xf* positive and *Xf* negative samples for each plant are reported in Table 1. Additionally, we detected *Xf* in 4 out of 62 BGSS samples.

We have sequenced the two most variable MLST genes for each of the positive plant and insect samples. Strains that possess one or more genes that manifest a uniquely different sequence in any of these genes are treated as a different strain. Our preliminary results have revealed different *Xf* strains in common native plant species and in BGSS collected from the same location. We have identified the Pierce's disease strain in *Vitis girdiana* (wild grape), *Pluchea odorata* (sweetscent) and three BGSS from a riparian area in Temecula, California. The multiplex strain was identified from *Xanthium strumarium* (cocklebur), *Salvia mellifera* (black sage) and a BGSS collected in Temecula. Additionally, *Salvia mellifera* collected from Emerson Oaks Reserve and on the UC, Riverside campus also contained the multiplex strain. However, *Encelia farinosa* (brittlebush) collected in the Riverside area (on the UC, Riverside campus and in Two Trees Trail (a riparian area near the UC, Riverside campus) contained a new variant of the multiplex strain.

CONCLUSIONS

Until recently, the identified strains in California have been those associated with agricultural or ornamental host plants. We do not know how many asymptomatic indigenous strains exist in California, especially in native or naturalized alien plants because they have not, as yet, given rise to a recognizable syndrome. Our plant collection and xylem extraction efforts have targeted native and naturalized plants in riparian habitats that may harbor *Xf* which is spread from them to cultivated plants by infected BGSS. Additionally, the possibility of invasions by novel strains from other parts of the Americas cannot be ignored. Therefore, it is critically important that we characterize the diversity of *Xf* strains present in California, especially those presumed to be the ancestral strains, i.e., those in native and naturalized alien plant hosts. This information is essential for fully understanding the potential for recombination and the generation of new and potentially more virulent strains.
